Abstract

In this paper we present a parsing architecture that allows processing of different mildly context-sensitive formalisms, in particular Tree-Adjoining Grammar (TAG), Multi-Component Tree-Adjoining Grammar with Tree Tuples (TT-MCTAG) and simple Range Concatenation Grammar (RCG). Furthermore, for tree-based grammars, the parser computes not only syntactic analyses but also the corresponding semantic representations.

1 Introduction

The starting point of the work presented here is the aim to implement a parser for a German TAG-based grammar that computes syntax and semantics. As a grammar formalism for German we chose a multicomponent extension of TAG called TT-MCTAG (Multi-component TAG with Tree Tuples) which has been first introduced by Lichte (2007). With some additional constraints, TT-MCTAG is mildly context-sensitive (MCS) as shown by Kallmeyer and Parmentier (2008).

Instead of implementing a specific TT-MCTAG parser we follow a more general approach by using Range Concatenation Grammars (RCG) as a pivot formalism for parsing MCS languages. Indeed the generative capacity of RCGs lies beyond MCS, while they stay parsable in polynomial time (Boullier, 1999). In this context, the TT-MCTAG (or TAG) is transformed into a strongly equivalent RCG that is then used for parsing. We have implemented the conversion into RCG, the RCG parser and the retrieval of the corresponding TT-MCTAG analyses. The parsing architecture comes with graphical input and output interfaces, and an XML export of the result of parsing. It is called TuLiPA (for “Tübingen Linguistic Parsing Architecture”) and is freely available under the GPL.\footnote{\url{http://sourcesup.cru.fr/tulipa/}}

In this paper, we present this parsing architecture focusing on the following aspects: first, we introduce the TT-MCTAG formalism (section 2). Then, we present successively the RCG formalism (section 3) and the conversion of TT-MCTAG into RCG (section 4). Section 5 shows how RCG is parsed in practice. Eventually, we present the retrieval of TT-MCTAG derivation structures (section 6), the computation of semantic representations (section 7) and optimizations that have been added to speed up parsing (section 8).

2 TT-MCTAG

TT-MCTAGs (Lichte, 2007) are multicomponent TAGs (MCTAG) where the elementary tree sets consist of one lexicalized tree $\gamma$, the head tree and a set of auxiliary trees $\beta_1, \ldots, \beta_n$, the argument trees. We write these sets as tuples $\langle \gamma, \{\beta_1, \ldots, \beta_n\} \rangle$. During derivation, the argument trees have to attach to their head, either directly or indirectly via node sharing. The latter means that they are linked by a chain of root-adjunctions to a tree adjoining to their head.
An MCTAG
\( (1) \) ... dass es der Mechaniker zu reparieren verspricht
... that the mechanic to repair promises
‘... that the mechanic promises to repair it’
\[ \text{Figure 1: TT-MCTAG analysis of (1)} \]
\[ \text{der Mech. } \]
\[ \text{verspricht } \]
\[ \text{reparieren } \]
\[ \text{NP_{acc}} \]
\[ \text{es} \]

**Definition 1 (TT-MCTAG)** An MCTAG \( G = (I, A, N, T, A) \) is a TT-MCTAG iff

1. every \( \Gamma \in A \) has the form \( \{ \gamma, \beta_1, \ldots, \beta_n \} \) where \( \gamma \) contains at least one leaf with a terminal label, the head tree, and \( \beta_1, \ldots, \beta_n \) are auxiliary trees, the argument trees. We write such a set as a tuple \( (\gamma, \{ \beta_1, \ldots, \beta_n \}) \).

2. A derivation tree \( D \) for some \( t \in L(I, A, N, T) \) is licensed as a TAG derivation tree in \( G \) iff \( D \) satisfies the following conditions (MC) (“multicomponent condition”) and (SN-TTL) (“tree-tuple locality with shared nodes”):

   (a) (MC) There are \( k \) pairwise disjoint instances \( \Gamma_1, \ldots, \Gamma_k \) of elementary tree sets from \( A \) for some \( k \geq 1 \) such that \( \bigcup_{i=1}^{k} \Gamma_i = \{ \} \) is the set of node labels in \( D \).

   (b) (SN-TTL) For all nodes \( n_0, n_1, \ldots, n_m, m > 1 \), in \( D \) with labels from the same elementary tree tuple such that \( n_0 \) is labelled by the head tree: for all \( 1 \leq i < m \): either \( \langle n_0, n_i \rangle \in \mathcal{P}_D \) or there are \( n_{i,1}, \ldots, n_{i,k} \) with auxiliary tree labels such that \( n_i = n_{i,k} \), \( \langle n_0, n_{i,1} \rangle \in \mathcal{P}_D \) and for \( 1 \leq j \leq k - 1 \): \( \langle n_{i,j}, n_{i,j+1} \rangle \in \mathcal{P}_D \) where this edge is labelled with \( \epsilon \).

TT-MCTAG has been proposed to deal with free word order languages. An example from German is shown in Fig. 1. Here, the \( \text{NP}_{\text{nom}} \) auxiliary tree adjoins directly to \( \text{verspricht} \) (its head) while the \( \text{NP}_{\text{acc}} \) tree adjoins to the root of a tree that adjoins to the root of a tree that adjoins to \( \text{reparieren} \).

For a more extended account of German word order using TT-MCTAG see Lichte (2007) and Lichte and Kallmeyer (2008).

TT-MCTAG can be further restricted, such that at each point of the derivation the number of pending \( \beta \)-trees is at most \( k \). This subclass is also called \( k \)-TT-MCTAG.

**Definition 2 (\( k \)-TT-MCTAG)** A TT-MCTAG \( G = (I, A, N, T, A) \) is of rank \( k \) (or a \( k \)-TT-MCTAG for short) iff for each derivation tree \( D \) licensed in \( G \):

(\( TT-k \)) There are no nodes \( n_i, h_0, \ldots, h_k, a_0, \ldots, a_k \) in \( D \) such that the label of \( a_i \) is an argument tree of the label of \( h_i \) and \( \langle h_i, n_i \rangle, \langle n_i, a_i \rangle \in \mathcal{P}_D \) for \( 0 \leq i \leq k \).

TT-MCTAG in general are NP-complete (Søgaard et al., 2007) while \( k \)-TT-MCTAG are MCS (Kallmeyer and Parmentier, 2008).

3 **RCG as a pivot formalism**

The central idea of our parsing strategy is to use RCG (Boullier, 1999; Boullier, 2000) as a pivot formalism.

**Definition 3 (RCG)** A RCG is a tuple \( G = \langle N, T, V, S, P \rangle \) such that a) \( N \) is an alphabet of predicates of fixed arities; b) \( T \) and \( V \) are disjoint alphabets of terminals and of variables; c) \( S \in N \) is the start predicate (of arity 1) and d) \( P \) is a finite set of clauses

\[ A_0(x_{01}, \ldots, x_{0a_0}) \rightarrow \epsilon, \]

or
\[A_0(x_{01}, \ldots, x_{0n}) \rightarrow A_1(x_{11}, \ldots, x_{11}) \ldots A_n(x_{n1}, \ldots, x_{n1})\]
with \(n \geq 1\), \(A_i \in N\), \(x_{ij} \in (T \cup V)^*\) and \(a_i\) being the arity of \(A_i\).

Since throughout the paper we use only positive RCGs, whenever we say “RCG”, we actually mean “positive RCG”. An RCG with maximal predicate arity \(n\) is called an RCG of arity \(n\).

When applying a clause with respect to a string \(w = t_1 \ldots t_n\), the arguments in the clause are instantiated with substrings of \(w\), more precisely with the corresponding ranges. The instantiation of a clause maps all occurrences of a \(t \in T\) in the clause to an occurrence of a \(t\) in \(w\) and consecutive elements in a clause argument are mapped to consecutive ranges.

If a clause has an instantiation wrt \(w\), then, in one derivation step, the left-hand side of this instantiation can be replaced with its right-hand side. The language of an RCG \(G\) is \(L(G) = \{w \mid S([0, |w|]) \Rightarrow \epsilon \ \text{wrt} \ w\}\).

A sample RCG is shown in Fig. 2.

**Figure 2**: Sample RCG

4 Transforming TT-MCTAG into RCG

The transformation of a given \(k\)-TT-MCTAG into a strongly equivalent simple RCG is an extension of the TAG-to-RCG transformation proposed by Boullier (1999). The idea of the latter is the following: the RCG contains predicates \(\langle \alpha \rangle(X)\) and \(\langle \beta \rangle(L, R)\) for initial and auxiliary trees respectively. \(X\) covers the yield of \(\alpha\) and all trees added to \(\alpha\), while \(L\) and \(R\) cover those parts of the yield of \(\beta\) (including all trees added to \(\beta\)) that are respectively to the left and the right of the foot node of \(\beta\). The clauses in the RCG reduce the argument(s) of these predicates by identifying those parts that come from the elementary tree \(\alpha/\beta\) itself and those parts that come from one of the elementary trees added by substitution or adjunction. An example is shown in Fig. 3.

\[\alpha_1 S_{NA} \quad \alpha_2 S_{FA} \quad \alpha_3 S_{FB} \quad \beta S_{NA} \]

**Equivalent RCG**:

\[S(X) \rightarrow \langle \alpha_1 \rangle(X) | \langle \alpha_2 \rangle(X) | \langle \alpha_3 \rangle(X)\]

\[\langle \alpha_1 \rangle(aF) \rightarrow \langle \alpha_2 \rangle(F) | \langle \alpha_3 \rangle(F)\]

\[\langle \alpha_1 \rangle(aB_1, B_2, F) \rightarrow \langle \beta \rangle(B_1, B_2) \langle \alpha_2 \rangle(F) | \langle \alpha_3 \rangle(F)\]

\[\langle \beta \rangle(B_1b, cB_2) \rightarrow \langle \beta \rangle(B_1, B_2)\]

\[\langle \alpha_2 \rangle(d) \rightarrow \epsilon | \langle \alpha_3 \rangle(e) | \epsilon | \langle \beta \rangle(b, c) \rightarrow \epsilon\]

**Figure 3**: A TAG and an equivalent RCG

For the transformation from TT-MCTAG into RCG we use the same idea. There are predicates \(\langle \gamma \rangle\) for the elementary trees (not the tuples) that characterize the contribution of \(\gamma\). We enrich these predicates in a way that allows to keep track of the “still to adjjoin” argument trees and constrain thereby further the RCG clauses. The pending arguments are encoded in a list that is part of the predicate name. The yield of a predicate corresponding to a tree \(\gamma\) contains not only \(\gamma\) and its arguments but also arguments of predicates that are higher in the derivation tree and that are adjoined below \(\gamma\) via node sharing. In addition, we use branching predicates \(adj\) and \(sub\) that allow computation of the possible adjunctions or substitutions at a given node in a separate clause.

As an example see Fig. 4. The first clause states that the yield of the initial \(\alpha_{rep}\) consists of the left and right parts of the root-adjoining tree wrapped around zu reparieren. The adj predicate takes care
of the adjunction at the root (address $\epsilon$). It states that
the list of pending arguments contains already
$\beta_{\text{acc}}$, the argument of $\alpha_{\text{rep}}$. According to the sec-
ond clause, we can adjoin either $\beta_{\text{acc}}$ (while re-
moving it from the list of pending arguments) or
some new auxiliary tree $\beta_v$.

The general construction goes as follows: We de-
define the decoration string $\sigma_\gamma$ of an elementary
tree $\gamma$ as in Boullier (1999): each internal node
has two variables $L$ and $R$ and each substitution
node has one variable $X$ ($L$ and $R$ represent the
left and right parts of the yield of the adjoined
tree and $X$ represents the yield of a substituted tree).

In a top-down-left-to-right traversal the left vari-
ables are collected during the top-down traversal,
the terminals and variables of substitution nodes
are collected while visiting the leaves and the right
variables are collected during bottom-up traversal.
Furthermore, while visiting a foot node, a separat-
ing “,” is inserted. The string obtained in this way
is the decoration string.

1. We add a start predicate $S$ and clauses
$S(X) \rightarrow (\alpha, \emptyset)(X)$ for all $\alpha \in I$.

2. For every $\gamma \in I \cup A$: Let $L_p, R_p$ be the left
and right symbols in $\sigma_\gamma$ for the node at posi-
tion $p$ if this is not a substitution node. Let
$X_p$ be the symbol for the node at position $p$ if this is a substitution node. We assume that
$p_1, \ldots, p_k$ are the possible adjunction sites,
$p_{k+1}, \ldots, p_l$ the substitution sites in $\gamma$. Then
the RCG contains all clauses
$\langle \gamma, LPA \rangle(\sigma_\gamma) \rightarrow$
$\langle adj, \gamma, p_1, LPA_{p_1} \rangle(L_{p_1}, R_{p_1})$
$\ldots$
$\langle adj, \gamma, p_k, LPA_{p_k} \rangle(L_{p_k}, R_{p_k})$
$\langle sub, \gamma, p_{k+1} \rangle(X_{p_{k+1}}) \ldots$
$\langle sub, \gamma, p_l \rangle(X_{p_l})$

such that

- if $LPA \neq \emptyset$, then $\epsilon \in \{p_1, \ldots, p_k\}$ and
$LPA \subseteq LPA_{\gamma}$, and
- $\bigcup_{i=0}^{k} LPA_{p_i} = LPA \cup \Gamma(\gamma)$ where
$\Gamma(\gamma)$ is either the set of arguments of $\gamma$
(if $\gamma$ is a head tree) or (if $\gamma$ is an argu-
ment itself), the empty set.

3. For all predicates $\langle adj, \gamma, dot, LPA \rangle$ the
RCG contains all clauses
$\langle adj, \gamma, dot, LPA \rangle(X, R) \rightarrow$
$\langle \gamma', LPA' \rangle(X, R)$
such that $\gamma'$ can be adjoined at position $dot$

- either $\gamma' \in LPA$ and $LPA' = LPA \setminus$
$\{\gamma\}$,
- or $\gamma' \notin LPA$, $\gamma'$ is a head (i.e., a head
tree), and $LPA' = LPA$.

4. For all predicates $\langle adj, \gamma, dot, \emptyset \rangle$ where $dot$ in
$\gamma$ is no OA-node, the RCG contains a clause
$\langle adj, \gamma, dot, \emptyset \rangle(\emptyset, \epsilon) \rightarrow \epsilon$.

5. For all predicates $\langle sub, \gamma, dot \rangle$ and all $\gamma'$
that can be substituted into position $dot$ in $\gamma$ the
RCG contains a clause
$\langle sub, \gamma, dot \rangle(X) \rightarrow \langle \gamma', \emptyset \rangle(X)$.

5 RCG parsing

The input sentence is parsed using the RCG com-
puted from the input TT-MCTAG via the conver-
sion algorithm introduced in the previous section.
Note that the TT-MCTAG to RCG transformation
is applied to a subgrammar selected from the in-
put sentence\(^5\), for the cost of the conversion is
proportional to the size of the grammar (all li-
censed adjunctions have to be computed while tak-
ing into account the state of the list of pending ar-
guments).\(^6\)

The RCG parsing algorithm we use is an exten-
sion of Boullier (2000). This extension concerns
(i) the production of a shared forest and (ii) the
use of constraint-based techniques for performing
some subtask of RCG parsing.

\(^5\)In other terms, the RCG conversion is done off-line.

\(^6\)We do not have a proof of complexity of the conversion
algorithm yet, but we conjecture that it is exponential in
the size of the grammar since the adjunctions to be predicted
depend on the adjunctions predicted so far and on the auxiliary
trees adjoinable at a given node.
of the structure, where entries are of the following form:

Miscellaneous for the RHS of each instantiated clause.

In other terms, we use a 3-dimensional tabulation so that not only boolean values are stored, but also the successful clause instantiations. In our parsing algorithm, we propose to extract this tabulation in such a way that not only boolean values (boolean) result of predicate and clause instantiation, but also the clause instantiations of the RHS predicate of the clause $i$.

Boullier’s algorithm lies in the tabulation of the input string. An interesting feature of Boullier’s algorithm is the tabulation of the (boolean) result of predicate and clause instantiations. In our parsing algorithm, we propose to extend this tabulation so that not only boolean values are stored, but also the successful clause instantiations for the RHS of each instantiated clause. In other terms, we use a 3-dimensional tabulation structure, where entries are of the following form:

\[ \Gamma[(i, \vec{\rho})][f_q^i][j] := (i_x, \vec{\rho}_x) \]

$\Gamma$ being a table storing the clause identifier and arguments $i_x$, $\vec{\rho}_x$ corresponding to the instantiation of the $j$th RHS predicate of the clause $i$ with the $q$th binding of arguments $\vec{\rho}$.

As a consequence of this extension, after parsing a shared forest can be straightforwardly extracted from the table of clause instantiations. This shared forest is represented by a context-free grammar, following Billot and Lang (1989). See Fig. 5 for an example.

### 5.1 Extracting an RCG shared forest

Boullier (2000) proposes a recognition algorithm relying on two interdependent functions: one for instantiating predicates, and one for instantiating clauses. Recognition is then triggered by asking for the instantiation of the start predicate with respect to the input string. An interesting feature of Boullier’s algorithm lies in the tabulation of the (boolean) result of predicate and clause instantiations. In our parsing algorithm, we propose to extend this tabulation so that not only boolean values are stored, but also the successful clause instantiations for the RHS of each instantiated clause.

In other terms, we use a 3-dimensional tabulation structure, where entries are of the following form:

\[ \Gamma[(i, \vec{\rho})][f_q^i][j] := (i_x, \vec{\rho}_x) \]

$\Gamma$ being a table storing the clause identifier and arguments $i_x$, $\vec{\rho}_x$ corresponding to the instantiation of the $j$th RHS predicate of the clause $i$ with the $q$th binding of arguments $\vec{\rho}$.

As a consequence of this extension, after parsing a shared forest can be straightforwardly extracted from the table of clause instantiations. This shared forest is represented by a context-free grammar, following Billot and Lang (1989). See Fig. 5 for an example.

### 5.2 Using constraints to instantiate predicates

A second extension of Boullier’s algorithm concerns the complex task of clause instantiation. During RCG parsing, for each clause instantiation, all possible bindings between the arguments of the LHS predicate and (a substring of) the input string must be computed. The more ranges with free boundaries the arguments of the LHS predicate contain, the more expensive the instantiation is. Boullier (2000) has shown that the time complexity of a clause instantiation is $O(n^d)$, where $n$ is length of the input string, and $d$ is the arity of the grammar (maximal number of free range boundaries). To deal with this high time complexity, Boullier (2000) proposes to use some predefined specific predicates\(^7\) whose role is to decrease the number of free range boundaries.

In our approach, we propose to encode the clause instantiation task into a Constraint Satisfaction Problem (CSP). More precisely, we propose to use constraints over finite sets of integers to represent the constraints affecting the range boundaries. Indeed, these constraints over integers offer a natural way of encoding constraints applied on ranges (e.g. linear order).

Let us briefly introduce CSPs. In a CSP, a problem is described using a set of variables, which take their values in a given domain. Constraints are then applied on the values these variables can take in order to narrow their respective domain. Finally, one (or all) solution(s) to the problem are searched for, that is to say some (or all) assignment(s) of values to variables while respecting the constraints are searched for. One particularly interesting subclass of CSPs are those that can be stated in terms of constraints on variables ranging over finite sets.

\(^7\)E.g. a length predicate is used to limit the length of the subpart of input string covered by a range.
of non-negative integers. For such CSPs, there exist several implementations offering a wide range of constraints (arithmetic, boolean and linear constraints), and efficient solvers, such as the Gecode library\(^8\) (Schulte and Tack, 2006).

In this context, the underlying idea of computing range instantiations as a CSP is the following. We use the natural order of integers to represent the linear order of ranges. More precisely, we compute all possible mappings between position indices in the input string (positive integers) and free range boundaries in the arguments of (the LHS predicate of) the clause to instantiate (variables taking their values in \([0..n]\), \(n\) being the length of the input sentence). Note that, within a given argument of a predicate to instantiate, a range of type \textit{constant} can be considered as a constraint for the values the preceding and following range boundaries can take, see the example Fig. 6 \((x_i\) are variables ranging over finite sets of integers and \(c_j\) are constants such that \(c_j = j\)).

\[(\text{LHS-})\text{Predicate instantiation:}\]
\[P(aXYdZ) \leftrightarrow P(abedef)\]

\[\text{Constraint-based interpretation:}\]
\[P(x_0 a x_1 X x_2 Y x_3 d x_4 Z x_5) \leftrightarrow P(c_0 a c_1 b c_2 c c_3 d c_4 e c_5 f c_6)\]
\[
\begin{align*}
  i & \leq j \Rightarrow x_i \leq x_j & \text{(linear order)} \\
  x_0 & = c_0 & x_5 & = c_0 & \text{(extern boundaries)} \\
  x_1 & = c_1 & x_3 & = c_4 & x_4 & = c_4 & \text{(anchor constraints)}
\end{align*}
\]

(here \(x_2\) is the only free range boundary, and can take 3 values, namely \(c_1, c_2\) or \(c_3\)).

Figure 6: Constraint-based clause instantiation.

The gain brought by CSP-based techniques remains to be evaluated. So far, it has only been observed empirically between 2 versions of the parser. Nonetheless constraints offer a natural framework for dealing with ranges.\(^9\)

Eventually, note that the extensions introduced in this section do not affect the time complexity of Boullier’s algorithm, which is \(O(|G|n^d)\), \(|G|\) being the size of the grammar, \(d\) its degree, and \(n\) the length of the input string.

\(^9\)The question of whether feature constraints should be used at this stage or not is discussed in section 6.

6 Retrieving TT-MCTAG derivation structures

As previously mentioned, the result of RCG-parsing is an RCG shared forest. In order to extract from this forest the TT-MCTAG derivation structure (namely the derivation and derived trees), we must first interpret this RCG forest to get the underlying TAG forest, and then expand the latter.

6.1 Interpreting the RCG shared forest

The interpretation of the RCG forest corresponds to performing a traversal of the forest while replacing all \textit{branching} clauses (i.e. clauses whose LHS predicate is labeled by \textit{adj} or \textit{sub}) by the \textit{tree} clause they refer to in the table of clause instantiation. In other terms, each instantiated branching clause is replaced by the tree clause corresponding to its unique RHS-predicate (see Fig. 7).

\[
\langle \alpha_{rep}, \emptyset \rangle \langle \text{es der Mech zu rep versp} \rangle 
\]
\[
\langle \text{adj}, \alpha_{rep}, \epsilon, \{ \beta_{acc} \} \rangle \langle \text{es der Mech, versp} \rangle 
\]
\[
\langle \text{adj}, \alpha_{rep}, \epsilon, \{ \beta_{acc} \} \rangle \langle \text{es der Mech, versp} \rangle 
\]
\[
\langle \text{adj}, \beta_{versp}, \epsilon, \{ \beta_{acc}, \beta_{nom} \} \rangle \langle \text{es der Mech, } \epsilon \rangle 
\]

\[
\sim \quad \langle \text{adj}, \epsilon \rangle 
\]

Figure 7: Relation between clause instantiations and TT-MCTAG derivation (using the TT-MCTAG in Fig. 1).

The result of this interpretation of the RCG shared forest is the TT-MCTAG shared forest, i.e. a factorized representation of all TT-MCTAG derivations as a context-free grammar. The extraction of this TT-MCTAG forest is done in a single traversal of the RCG forest (i.e. of the table of clause instantiations) starting from the clause whose LHS predicate is the start predicate. Since the predicate names contain the tree identifiers they refer to, no lookup in the grammar is needed. As a consequence, the time complexity of the extraction of the TT-MCTAG forest is bound by the size of the table of clause instantiations.

Note that (i) we do not expand the alternatives resulting from syntactic ambiguity at this stage,
and (ii) both the RCG and TT-MCTAG derivation forests have been computed without taking the feature structures into account. The motivation is to delay the cost of unification to the final step of expansion of the TT-MCTAG forest. Indeed, the word order constraints encoded in the RCG have possibly rejected many ungrammatical structures for which the cost of feature unification would have been wasted time. It would be interesting to experiment whether we would benefit or not from using feature structures as additional constraints on clause instantiation in practice.

6.2 Expanding the TAG shared forest

Finally, from this TT-MCTAG derivation forest, we can extract all derivation trees, and then compute the corresponding derived trees.

This task amounts to traversing the forest in a top-down-fashion, using the information in the encountered nodes (referring to elementary trees) to gradually assemble derivation trees. Some nodes in the forest encode a syntactic ambiguity (disjunctive node), in which case we make a copy of the current derivation tree and apply one of the alternative options to each of the trees before following each branch through. This behavior is easy to implement using a FIFO queue. A few control mechanisms check for integrity of the derivation trees during the process. We end up with a set of derivation trees in an XML DOM format that can either be displayed directly in the GUI or exported in an XML file.

For reasons of flexibility, we chose to rely on an XML DOM internal representation for all the steps of derived tree building. Indeed, this enables each of the derivation steps to be displayed directly in the GUI through the process. Feature unification also happens at this point, allowing for a graphical illustration of feature clashes in the parse tree in debug mode.

7 Computing semantics

The parsing architecture introduced here has been extended to support the syntax/semantics interface of Gardent and Kallmeyer (2003). The underlying idea of this interface is to associate each tree with flat semantic formulas. The arguments of these formulas are unification variables co-indexed with features labelling the nodes of the syntactic tree. During derivation, trees are combined via adjunction and/or substitution, each triggering the unifications of the feature structures labelling specific nodes. As a result of these unifications, the arguments of the semantic formulas associated with the trees involved in the derivation get unified. In the end, each derivation/derived tree is associated with a flat semantic representation corresponding to the union of the formulas associated with the elementary trees that have been used. An example is given in Fig. 8.

8 Optimizations

The parsing architecture presented here can host several optimizations. In this section, we present two examples of these. The first one concerns lexical disambiguation, the second one RCG parsing.

Lexical disambiguation becomes a necessity because, for each token of the input sentence, there may be many candidate elementary trees, each of these being used in the RCG conversion, thus leading to a combinatorial explosion for longer sentences. We tackled this problem using the technique introduced in Bonfante et al. (2004). The idea behind their approach is to encode all the possible combinations of elementary trees in an automaton. For this purpose, elementary trees are first reduced to sets of polarity values depending on the resources and needs they represent (a substitution or foot node refers to a need for a certain category, while a root node corresponds to a re-

---

7 Recall that all licensed adjunctions are predicted.
source). For example, an S elementary tree with two places for NP substitution has an NP polarity of -2 and an S polarity of +1. Using this representation, every candidate elementary tree is represented by an edge in an automaton built by scanning the input sentence from left to right. The polarity of a path through the automaton is the sum of all the polarities of the edges encountered on the way. While building this automaton, we determine all the paths with a neutral polarity for every category but the parsed constituent’s category (whose polarity is +1). Such a path encodes a set of elementary trees that could contribute to a valid parse. As a consequence, the parser only has to consider for RCG conversion, combinations for a small number of tree sets. This approach makes the search space for both RCG conversion and RCG parsing much more manageable and leads to a significant drop in parsing time for some long sentences.

The second optimization concerns RCG parsing, which can have a high cost in cases where there are many free range boundaries. We can decrease the number of such boundaries by adding a constraint preventing range variables referring to substitution nodes from being bound to ϵ.

9 Conclusion and future work

In this paper, we introduced a parsing environment using RCG as a pivot formalism to parse mildly context-sensitive formalisms such as TT-MCTAG. This environment opens the way to multi-formalism parsing. Furthermore, its modular architecture (RCG conversion, RCG parsing, RCG shared forest interpretation) made it possible to extend the system to perform additional tasks, such as semantic calculus or dependency structure extraction. The system is still being developed, but is already used for the development of a TT-MCTAG for German (Kallmeyer et al., 2008). Future work will include experiments with off-line conversion of TT-MCTAG and generalization of branching clauses to reduce the size of the RCG and thus to improve (RCG) parsing time.
